Linearization and purely imaginary eigenvalues

What is special about the case of purely imaginary eigenvalues in the linearization?

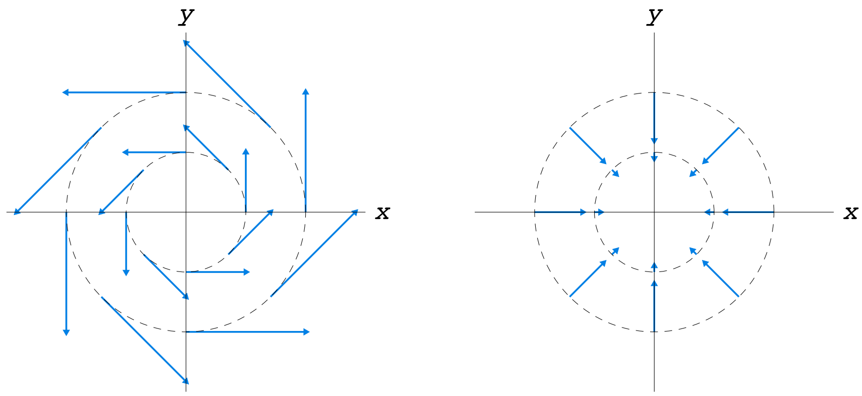
Example. Consider the one-parameter family of systems

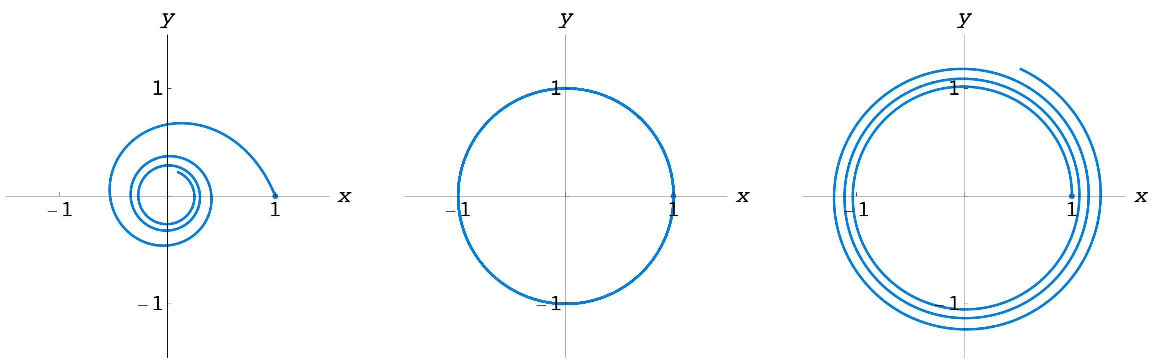
$$\begin{aligned} \frac{dx}{dt} &= -y + \alpha x(x^2+y^2) \\ \frac{dy}{dt} &= \quad x + \alpha y(x^2+y^2) \end{aligned}$$

where α is a parameter. Note that $(0,0)$ is always an equilibrium point.

Consider the vector field as the sum of the two vector fields

$$\mathbf{J}\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -y \\ x \end{pmatrix} \qquad \text{and} \qquad \mathbf{R}\begin{pmatrix} x \\ y \end{pmatrix} = \alpha(x^2+y^2)\begin{pmatrix} x \\ y \end{pmatrix}.$$





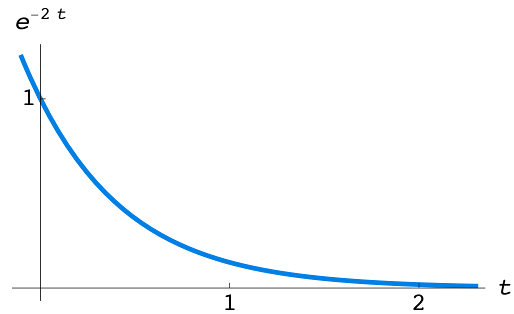
The Laplace transform

For the remainder of the semester, we are going to take a somewhat different approach to the solution of differential equations. We are going to study a way of transforming differential equations into algebraic equations.

We begin with a little review of improper integrals.

Example. Consider the improper integral

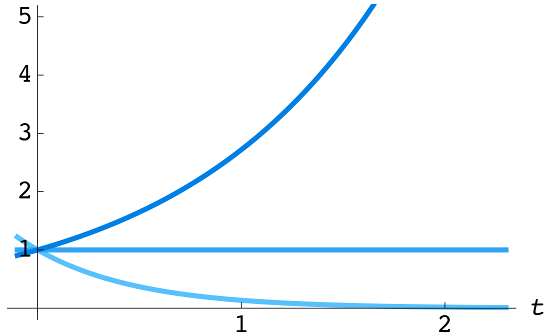
$$\int_0^\infty e^{-2t}\,dt.$$



Example. Consider the improper integrals

$$\int_0^\infty e^{-st}\,dt$$

for various values of s.



Definition. The *Laplace transform* of the function $y(t)$ is the function

$$Y(s) = \int_0^\infty y(t)\,e^{-st}\,dt.$$

This transform is an "operator" (a function on functions). It transforms the function $y(t)$ into the function $Y(s)$.

Notation: We often represent this operator using the script letter $\mathcal{L}$. In other words,

$$\mathcal{L}[y] = Y.$$

For example, $\mathcal{L}[1] = \dfrac{1}{s}$.

Note that, even if $y(t)$ is defined for all t, the Laplace transform $Y(s)$ may not be defined for all s.

Example. Let's compute $\mathcal{L}[e^{at}]$ using the definition and the improper integrals we have already computed:

Examples. Using *Mathematica* to calculate the improper integrals, we see that:

$$\mathcal{L}[\sin t] = \frac{1}{s^2+1} \quad \text{for} \quad s > 0$$

$$\mathcal{L}[e^{2t}\sin 3t] = \frac{3}{s^2-4s+13} \quad \text{for} \quad s > 2$$

$$\mathcal{L}[t^4] = \frac{24}{s^5} \quad \text{for} \quad s > 0$$

$$\mathcal{L}[\sin 2t] = \frac{2}{s^2+4} \quad \text{for} \quad s > 0,$$

$$\mathcal{L}[t\,\cos\sqrt{2}\,t] = \frac{s^2-2}{(s^2+2)^2} \quad \text{for} \quad s > 0$$

$$\mathcal{L}[e^{i\omega t}] = \frac{1}{s-i\omega} \quad \text{for} \quad s > 0$$

Properties of the Laplace transform There are two properties of the Laplace transform that make it well suited for solving linear differential equations:

1. $\mathcal{L}\left[\frac{dy}{dt}\right] = s\mathcal{L}[y] - y(0)$
2. $\mathcal{L}$ is a linear transform

Both of these properties are extremely important, but the surprising one is #1. Let's consider

$$\mathcal{L}\left[\frac{dy}{dt}\right] = \int_0^\infty \left(\frac{dy}{dt}\right) e^{-st}\,dt.$$

In fact, before we consider the improper integral, let's apply the method of integration by parts to the indefinite integral

$$\int \left(\frac{dy}{dt}\right) e^{-st}\,dt.$$

Now let's see how we can use the Laplace transform to solve an initial-value problem.

Example. Solve the IVP

$$\frac{dy}{dt} - 3y = e^{2t}, \quad y(0) = 4.$$

1. Transform both sides of the equation:

2. Solve for $\mathcal{L}[y]$:

3. Calculate the inverse Laplace transform:

Is this the right answer? Do we need Laplace transforms to calculate it?
